## Abstract

The U.S. Geological Survey, in cooperation with the U.S. Fish and Wildlife Service collected data on water and bottomsediment chemistry to be used to evaluate a new water rights acquisition program designed to enhance wetland habitat in Stillwater National Wildlife Refuge and in Lahontan Valley, Churchill County, Nevada. The area supports habitat critical to the feeding and resting of migratory birds travelling the Pacific Flyway. Information about how water rights acquisitions may affect the quality of water delivered to the wetlands is needed by stakeholders and Stillwater National Wildlife Refuge managers in order to evaluate the effectiveness of this approach to wetlands management. A network of six sites on waterways that deliver the majority of water to Refuge wetlands was established to monitor the quality of streamflow and bottom sediment. Each site was visited every 4 to 6 weeks and selected water-quality field parameters were measured when flowing water was present. Water samples were collected at varying frequencies and analyzed for major ions, silica, and organic carbon, and for selected species of nitrogen and phosphorus, trace elements, pharmaceuticals, and other trace organic compounds. Bottom-sediment samples were collected for analysis of selected trace elements.

Dissolved-solids concentrations exceeded the recommended criterion for protection of aquatic life (500 milligrams per liter) in 33 of 62 filtered water samples. The maximum arsenic criterion (340 micrograms per liter) was exceeded twice and the continuous criterion was exceeded seven times. Criteria protecting aquatic life from continuous exposure to aluminum, cadmium, lead, and mercury (87, 0.72, 2.5, and 0.77 micrograms per liter, respectively) were exceeded only once in filtered samples (27, 40, 32, and 36 samples, respectively). Mercury was the only trace element analyzed in bottom-sediment samples to exceed the published probable effect concentration (1,060 micrograms per kilogram).

# Introduction

Stillwater National Wildlife Refuge (SNWR), located in the Carson Desert hydrographic area (Rush, 1968; known locally as Lahontan Valley) consists of a complex system of flow-through and terminal wetlands and ponds in the internally drained Carson River Basin in west-central Nevada (fig. 1). The surrounding high desert Great Basin is characterized as arid, making wetland habitat critical to the feeding and resting of migratory birds protected under the 1918 Migratory Bird Treaty Act (16 U.S.C. 703-712; Ch. 128; July 13, 1918; 40 Stat. 755). The area is also recognized as an important habitat for the Western Hemisphere Shorebird Reserve Network (https://www.whsrn.org/lahontan-valley-wetlands), a "Globally Important Bird Area" by the American Bird Conservancy (http://www.abcbirds.org/abcprograms/domestic/iba/index. html), and an "Important Bird Area" by the National Audubon Society (http://www.audubon.org/important-bird-areas/ lahontan-valley-wetlands). However, although water availability is the primary limiting factor for wetland management in Lahontan Valley (Engilis and Reid, 1996), potentially toxic contaminants associated with mining, milling, and irrigation drainage have been shown to adversely affect the ecological health of the area (Hallock and Hallock, 1993; Higgins and Miesner, 2002). Due to their persistence, trace organic compounds (TOCs) associated with treated domestic and industrial wastewater effluent, urban runoff, and leachate from livestock and dairy operations also may affect the ecological health of SNWR (Battaglin and Kolok, 2014) and potentially accumulate in the internally drained watershed.

Concern for the quality and related adverse effects of drainage from irrigated agriculture in the western United States led the Department of the Interior (DOI) to investigate the nature and extent of water-quality problems in National Wildlife Refuges and other areas that receive irrigation drainage from DOI irrigation facilities (Hoffman and others, 1990). Many of the wetlands in Lahontan Valley were found to be adversely affected by hydrological and geochemical processes related to the Newlands Irrigation Project area, with water collected from some agricultural drains found to be acutely toxic to aquatic organisms (Hallock and Hallock, 1993;

**Figure 1.** Location of selected hydrologic features and wastewater treatment facilities in the Carson River Basin, Stillwater National Wildlife Refuge and Carson Desert (Lahontan Valley) hydrographic area, Nevada.

Hoffman, 1994; Higgins and Miesner, 2002). Concentrations of dissolved solids, arsenic, boron, lithium, and molybdenum were found to increase in oxygenated water applied to irrigate alkaline agricultural fields due to dissolution and desorption of naturally occurring trace elements (Lico, 1992; Hoffman, 1994).

In addition, the lower Carson River floodplain downstream of Carson City has been on the Federal Superfund National Priority List since 1990 due to mercury contamination from historical milling and amalgamation of silver and gold ore mined from the Comstock Lode (https://yosemite.epa.gov/r9/ sfund/r9sfdocw.nsf/vwsoalphabetic/Carson+River+Mercury +Site?OpenDocument). For uncertain reasons, the toxicity of mercury to SNWR wildlife has not been as severe as effects reported for wetlands affected by mercury contamination outside of Lahontan Valley (Henny and Herron, 1989; U.S. Fish and Wildlife Service, 2002; Hill and others, 2008).

Recognizing the environmental decline in critical wetland habitat, Congress included provisions in the 1990 Truckee-Carson-Pyramid Lake Water Rights Settlement Act (Title II of Public Law 101-618; the Act) to assist with restoration and maintenance of wetland ecosystems in Lahontan Valley (Neel and Henry, 1996). The Act authorized the Secretary of the Interior to purchase water rights needed to support a longterm average of 25,000 acres of wetland habitat, including 14,000 acres within SNWR (Tuttle and others, 2001). The U.S. Fish and Wildlife Service (USFWS) implemented a program in 1996 to purchase up to 75,000 acre-feet of water from the Carson Division of the Newlands Project. However, as presently enacted, the water rights acquisition program amount is much less than the 270,000 acre-feet per year estimated to have flowed into Lahontan Valley wetlands during average years before the Newlands Reclamation Project began in 1905 (Kerley and others, 1993). The purposes of acquiring water rights were to ensure that wetland habitat is available during non-drought years and improve the quality of water delivered to the refuge (U.S. Fish and Wildlife Service, 2002). The USFWS has also acquired rights to treated wastewater effluent, and the Truckee Meadows Water Reclamation Facility (TMWRF) is permitted to discharge treated effluent upstream of Derby Dam and the Truckee Canal. The feasibility of using treated municipal wastewater to improve or create wetlands is specified in the Act. To evaluate the effectiveness of this

approach to wetland management, information about the quality of water currently being delivered to the wetlands is needed by stakeholders and SNWR managers.

#### Purpose and Scope

The purpose of this report is to provide data on the quality of water and bottom-sediment samples collected during 2014–16 and provide comparison to historical data in order to inform decision-makers about the water delivered to SNWR for wetland enhancement. The scope of the study focuses on the quality of water and bottom sediment collected from the primary inflows to SNWR. Samples collected during 2014–16 were analyzed for a comprehensive suite of analytes that included dissolved solids, major ions, organic carbon, nitrogen, phosphorus, and more than 100 trace organic compounds associated with treated wastewater effluent, as well as selected constituents with aquatic-life criteria. Historical data collected before implementation of the water rights acquisition program (1971–98) also are presented and when appropriate, compared to the 2014–16 data.

#### **Description of Study Area**

The SNWR occupies an area of about 79,570 acres in Lahontan Valley (fig. 1). Precipitation in the Carson Desert is negligible (less than 5 inches per year; http://www.usclimatedata.com/climate/fallon/nevada/united-states/usnv0028) compared to amounts that typically fall in the Sierra Nevada headwaters of the Carson and Truckee Rivers (40 inches per year; Maurer and Berger, 2007). Thus, virtually all of the inflow to SNWR originates as runoff to the Carson River plus diversions from the Truckee River via the Truckee Canal. Annual runoff statistics for selected U.S. Geological Survey (USGS) streamflow gaging stations highlight the range between wet years (maximums) and dry years (minimums), how maximums can skew mean values above median values, and how the Sierra Nevada rain shadow affects runoff contributions from eastern sub-basins of the drainage area (table 1). Runoff at the Truckee Canal station is the exception because it is regulated by diversions from the Truckee River at Derby Dam.

Prior to river diversions for irrigated agriculture and milling of ore and timber, the Lahontan Valley wetlands expanded and contracted in response to the natural variability in streamflow of the Carson River. Exceptionally wet periods would inundate much of Carson Sink and Lahontan Valley with water, creating a relatively shallow lacustrine habitat, whereas extended droughts resulted in isolated wetlands maintained by intercepted groundwater. Introduction of irrigated agriculture increased the distribution of groundwater recharge and evapotranspiration in the upper drainage basin and delayed streamflow to Lahontan Valley wetlands.

The Newlands Project was one of the first irrigation projects to be financed under the Reclamation Act and included construction of Derby Dam, Truckee Canal, Lahontan Dam and Reservoir, and a network of irrigation canals, laterals, and drains for irrigated agriculture (figs. 1 and 2). The interbasin transfer of Truckee River water occurs by the conveyance of river water through the Truckee Canal to Lahontan Reservoir on the Carson River. Since 1915, water from the Carson River and the Truckee Canal has been stored in Lahontan Reservoir to support crop irrigation through the typically arid growing season in Lahontan Valley. However, in spite of more than 100,000 acre-feet of water delivered to the reservoir from the Truckee River, estimated total wetland acreage in Lahontan Valley has been reduced from 150,000 acres prior to agricultural development in 1860 to 15,000 acres in 1992 (Hallock and Hallock, 1993). Wetland acreage varies considerably from year to year and unusually wet years can result in inundation of wetlands that are not considered to be viable habitat in normal water years due to irrigation diversions.

The Carson River Diversion Dam is located about 5 miles downstream of Lahontan Reservoir (https://www.usbr.gov/ projects/index.php?id=52) (fig. 2). Most of the water released from the Diversion Dam is diverted through the "T Line" Canal on the north side of the river and the "V Line" Canal on the south side. Within Lahontan Valley, a 68-mile network of arterial canals distributes water to more than 300 miles of Newlands Reclamation Project lateral canals that irrigate about 55,000 acres of hay and forage crops. Nearly 350 miles of drains mitigate water-logging of crops and also convey water to other fields and to SNWR, and other wetlands. During wet years, water is allowed to flow out to the Carson Sink, which is the terminus of the internally drained Carson River.

Water availability is acknowledged as the primary limiting factor for wetland management in Lahontan Valley (Engilis and Reid, 1996). Natural variability in streamflow and an arid climate, coupled with competing demands for agriculture, public supplies, and endangered and threatened species have significantly changed the timing and reduced the volume and rate of water flowing into SNWR. Reduced water availability may also affect water quality and wetland habitat.

Approximately 7,500 tons of elemental mercury were lost during the Comstock milling boom (Smith, 1943; Bailey and Phoenix, 1944), making mercury possibly the greatest hazard to SNWR wetland ecosystems (U.S. Fish and Wildlife Service, 2002). During the peak of the boom (about 1860–1900) the Carson River flowed freely into Lahontan Valley until construction of Lahontan Dam and Reservoir in 1915. However, some mercury continues to reach SNWR (Wayne and others, 1996), and samples of water, bottom sediment, and food-web organisms have showed elevated concentrations of mercury in excess of fish and wildlife effect levels (Cooper, 1983; Hoffman and Thomas, 2000; Tuttle and others, 2001). Mercury methylation has been shown to be stimulated in wetlands and the process may be associated with wetland emergent vegetation (Windham-Meyers, 2009). However, toxicity of mercury to SNWR wildlife has not been as severe as effects reported for other mercury contaminated wetlands outside of Lahontan Valley (Henny and Herron, 1989; U.S. Fish and Wildlife Service, 2002; Hill and others, 2008) for yet unknown reasons.

Concentrations of un-ionized ammonia and 12 trace elements have been reported at levels of concern in water, bottom sediment, and biological samples. Aluminum, arsenic, boron, and mercury were identified as the contaminants of greatest concern. Mercury and selenium were found to be transported with living algae and organic detritus suspended in irrigation drainage, and bioaccumulated as much as 10,000 fold in invertebrates when compared to concentrations in water (U.S. Fish and Wildlife Service, 2002). Concentrations of boron, mercury, and selenium also were higher than published adverse effect levels in several juvenile migratory birds (Hallock and Hallock, 1993). The health of the aquatic food web may be at risk due to possible effects of long-term mercury exposure combined with other trace elements (U.S. Fish and Wildlife Service, 2002), pesticides, and other organic compounds (Kilroy and Watkins, 1997; Schoenfuss and others, 2016).

Trace organic compounds, including antibiotics, human and veterinary pharmaceuticals, fragrances, detergents, fire retardants, disinfectants, and insect repellants are a new focus for environmental research because they are increasingly being detected in the environment (Kolpin and others, 2002; Barnes and others, 2002; Furlong and others, 2014) and also may affect the ecological health of SNWR. Recent advances in analytical methods are now allowing for the measurement of TOCs at concentrations as low as a few parts per trillion, and although they are found in relatively low concentrations, they are increasingly being detected in the environment large distances from municipal wastewater treatment facilities (Furlong and others, 2014). Currently there is little information regarding the toxicological significance of TOCs in ecosystems, particularly effects from long-term, low-level exposures in an aquatic environment affected by other contaminants, but many are known or suspected to disrupt endocrine systems of aquatic organisms (Daughton and Ternes, 1999).

Figure 2. Location of selected hydrologic features, and water and bottom-sediment sampling sites in and near Stillwater National Wildlife Refuge, Lahontan Valley, Nevada.

## Methods

#### Site Selection and Field Measurements

For the purposes of this investigation, six sites on waterways (fig. 2; table 2) identified by the USFWS to deliver the majority of water to SNWR wetlands were established or re-activated as surface-water monitoring stations in the USGS National Water Information System (NWIS) for data storage, access, and archiving. Historical data were collected as early as 1967 at site 5 to provide information about water deliveries from the Newlands Reclamation Project to SNWR, and sites 1, 2, 4, and 6 were established during the DOI National Irrigation Drainage investigation of Lahontan Valley wetlands between 1986 and 1998. Site 3 was established in 2013 on a canal recently constructed to bypass Stillwater Point Reservoir due to inadequate wetland habitat. Graduated staff plates and creststage gages were installed at each site as points of reference for monitoring and as a stable datum to relate stream stage to intermittently measured streamflow and as an indicator of peak streamflow, respectively (Sauer and Turnipseed, 2010; Turnipseed and Sauer, 2010).

Sites were visited about every 6 weeks, and when flowing water was observed, gage height was recorded and instantaneous streamflow was measured using acoustic Doppler methodology with graduated tagline and wading rod (Turnipseed and Sauer, 2010). Water-quality field parameters (temperature, specific conductance, pH, Eh, and dissolved oxygen) were measured using a calibrated multiparameter meter and water-quality probes according to standard USGS protocols (U.S. Geological Survey, variously dated) and manufacturer specifications. Alkalinity, bicarbonate, and carbonate were determined for water samples within 24 hours of sample collection by inflection point-digital titration with sulfuric acid following USGS protocols (U.S. Geological Survey, variously dated; Rounds, 2012).

#### Collection and Processing of Surface-Water and Bottom-Sediment Samples

Sampling equipment was cleaned prior to sample collection following procedures described by Wilde (2004). Samples of flowing water were collected using a DH81 standard handheld, depth-integrating sampler following the equal-widthincrement method (U.S. Geological Survey, 2006). When flow was minimal, grab samples were collected from the middle of the channel using a clean, 1-liter polyethylene wide-mouth bottle (Wilde and others, 2004; U.S. Geological Survey, 2006). A minimum of six sub-samples collected from designated locations along the stream, canal, or ditch cross section were composited in a clean polypropylene churn splitter used to fill clean sample bottles with homogenized unfiltered sample water.

After processing unfiltered samples from the churn, sample water for TOC analysis was drawn into a sample-rinsed disposable, 20-milliliter (mL) polypropylene syringe fitted with a disposable 25-millimeter (mm), 0.7-micron nominal pore diameter, glass fiber filter from which water was forced through into a 20-mL amber glass vial. Sample vials were sealed with a septa cap and bagged, and immediately chilled to 4 °C in an ice-filled cooler. A variable-speed peristaltic pump was used to process the remaining samples from the composited water in the churn through tygon tubing and disposable 0.45-micron capsule filters into clean sample bottles. Prior to sample processing, capsule filters were pre-rinsed with 2 liters of de-ionized water to leach any residual trace elements that may be associated with the filter as determined from the manufacturer. Teflon sample bottles and quality-assured hydrochloric acid used during the processing of mercury samples were provided by the USGS Wisconsin Mercury Research Laboratory (WMRL). Samples for filtered and unfiltered mercury and methylmercury analysis were preserved to 1 percent (volume of preservative added per sample volume) with hydrochloric acid. Samples for determination of major cations and trace elements were treated with Ultrex 7.7N nitric acid to a pH of less than 2. Water samples collected for determination of unfiltered concentrations of nitrogen and phosphorus species and filtered organic carbon were treated with 4.5N sulfuric acid to a pH of less than 2. Immediately following sample processing, all samples were stored away from direct sunlight and chilled to 4 °C in ice-filled coolers. Major constituents, selected species of nitrogen and phosphorus, and selected trace element samples

**Table 2.**Sampling sites selected for collection of water and bottom-sediment samples,Stillwater National Wildlife Refuge, Lahontan Valley, Nevada.

Map number (figure 2)	U.S. Geological Survey site number	Site name	Year site established
1	10312190	Lower Diagonal Drain at Highway 50	1986
2	1031220130	Harmon Reservoir Outflow	1998
3	103122155	Stillwater Point Reservoir Bypass Canal	2013
4	1031221902	S-Line Diversion Canal	1991
5	10312220	Stillwater Slough Cutoff Drain	1967
6	10312277	Paiute Drain below TJ Drain	1986

were delivered by overnight courier to the USGS National Water Quality Laboratory (NWQL) in Lakewood, Colorado. Samples for determination of total and filtered mercury and methylmercury were shipped overnight to the USGS WMRL in Middleton, Wisconsin.

Samples of bottom sediment were collected from the top 1 to 2 inches of sediment at five to seven randomly distributed depositional areas along a 300-foot reach of channel, passed through a 2-mm polyethylene mesh sieve, and thoroughly composited in a pre-cleaned glass bowl before being transferred into 500-mL acid-rinsed, clear polypropylene widemouth jars that were packed in ice-filled coolers for overnight shipment to the NWQL (Radtke, 2005). These samples were analyzed for concentrations of arsenic, boron, cadmium, chromium, copper, iron, lead, manganese, molybdenum, nickel, selenium, and zinc. Bottom-sediment samples collected for analysis of total and methylmercury were transferred into 30-mL vials that were packed in coolers with dry ice for overnight shipment to the WMRL. A list of analytical methods and references describing the methods used to analyze samples for the various constituents evaluated as part of this study is shown in table 3.

#### Quality Assurance

U.S. Geological Survey procedures, standards, and policies documented in the USGS National field manual for the collection of water-quality data (U.S. Geological Survey, variously dated) were followed to ensure results were not affected by sample collection procedures. As standard laboratory practice, both the USGS National Water Quality Laboratory (http://wwwnwql.cr.usgs.gov/qas.shtml?qcm) and the USGS Mercury Research Laboratory (http://wi.water.usgs.gov/ mercury-lab/quality-assurance-manual.html#12) follow documented analytical quality assurance/quality control protocols. Quality assurance samples were collected to assess variability and bias resulting from sample collection, processing, handling, and laboratory analysis.

On November 5, 2013, and May 14, 2014, equipment blanks were processed in the USGS Nevada Water Science Center laboratory to evaluate the effectiveness of the equipment cleaning process. On June 1, 2015, field-blank samples were processed at the Stillwater Point Reservoir Bypass Canal site to ensure that field conditions and sample processing procedures were not introducing any of the analytes into the samples (table 4). Analytical results for two split-replicate water samples, two submissions of National Institute of Standards and Technology (NIST; 2011) Standard Reference Material SRM 1944, New York/New Jersey waterway sediment, and one split-replicate of a bottom-sediment sample collected from the S-Line Diversion Canal are listed in table 5. The NIST reference material was treated with inorganic-free blank water to submit the sample as a sediment rather than a soil to the laboratory. The same inorganic-free blank water was used to process field blanks evaluated for aqueous inorganic constituents (table 4).

The percent relative difference (%RD) was used to evaluate the difference in analytical results between the replicate samples and the analytical results of the SRM material provided by the laboratory, and certified values available from NIST (table 5). To assess variability, gross laboratory processing errors, and other problems related to sample-matrix interferences, surrogate trace organic compounds with chemical and physical properties similar to compounds targeted by laboratory analyses, but not normally found in environmental water, were added to the samples by the NWQL prior to analysis. The results of these surrogate analyses are reported in table 6 as the percentage of the spiked mass recovered.

Analytical results reported for two equipment blank water samples processed for trace metals were less than laboratory reporting limits except for both filtered and unfiltered mercury and methylmercury, where concentrations were measured at the laboratory reporting limits (0.06 and 0.04 ng/L, respectively) for these constituents (table 4*C*). The concentration of nicotine in the field blank sample was reported as detected (34.5 ng/L), but at a level still less than the laboratory reporting limit of 58 ng/L (table 4*D*).

Generally, the variability between replicate-sample analyses is evaluated by calculating the percent relative difference between the sample concentrations, and is presumed acceptable when the difference between the measurements is plus or minus 20 percent, which most replicate analyses satisfy (table 5). Unfiltered concentrations of organic carbon, chromium, and nickel, and filtered concentrations of iron and nickel exceeded the 20-percent criteria by 5 percent or less. Unfiltered ammonia and filtered selenium each had relative differences between 25 and 35 percent, and the relative difference between duplicate filtered manganese analyses was 68 percent. The percent relative difference between analytical results for lidocaine, commonly found in topical anesthetics, was more than 160 percent; however, relative differences often are higher when concentrations are near the limits of an analytical method.

Analytical results of percent recovery reported for 19 trace organic compound surrogates added by the NWQL (table 6) indicate that although most averaged within plus or minus 20-percent recovery, most also exhibited outliers in individual sample analyses. Diltiazem-d3 showed the greatest variability with a maximum recovery of 190 percent and a minimum of 55.4 percent. Median and mean recoveries of sulfamethoxazole (phenyl-13C6) were both more than 130 percent with all 16 analyses reported as more than 100 percent. Fluoxetine-d6 (59.7 percent) and diphenhydramined3 (53.3 percent) also had very low recoveries. No individual sample disproportionally accounted for outlying results, indicating various matrix interferences may affect each surrogate differently, and some surrogates are known as poor performers for specific analytical methods (Angela Paul, U.S. Geological Survey, written comm., April 14, 2017).

Constituents analyzed in water and bottom-sediment samples, and referenced laboratory analytical methods. Table 3.

## Results

A statistical summary of the results of field and laboratory analytical measurements is shown in table 7, and all of the data from individual samples are listed in tables 10 to 15 in the supplemental data section. Data in table 7 are grouped as before (pre-program) and after (post-program) the initiation of the water rights acquisition program. Factors, including changed reporting limits, varying contributions of groundwater to streamflow, drought, and seasonal differences may be influencing these results. Aquatic-life criteria promulgated for designated water in the State of Nevada and recommended by the U.S. Environmental Protection Agency are listed for selected constituents in table 8.

Statistical distributions and the number of observations of selected water-quality parameters and solutes measured in pre-program (1971–98) site visits are compared graphically to those measured in post-program (2014–16) visits on figures 3 to 5. Also included with each graph are charts of the number of measurements made at each of the six monitoring sites to indicate the relative influence individual sites may have on each dataset. Mean, median, and maximum values of field measurements (table 7*A*; fig. 3) indicate minimal differences in temperature (fig. 3*A*), specific conductance (fig. 3*B*), dissolved oxygen (fig. 3*C*), pH (fig. 3*D*), and alkalinity (fig. 3*E*), but show measurable decreases in instantaneous streamflow measurements (fig. 3*F*).

Concentrations of dissolved solids and major ions (chloride, sulfate, potassium, calcium, magnesium, and sodium; fig. 4) in the pre-program dataset include maximum concentrations that were much larger than values measured in samples collected during the post-program, but minimum concentrations are nearly identical (table 7*B*). This may be due in part, to more samples being collected from Paiute Drain in the pre-program dataset than in the post-program dataset.

Total nitrogen data indicate decreased concentrations between pre- and post-programs, but the difference in phosphorus concentrations is small except for one outlier in the post-program dataset (table 7*C*).

Over time, methods of analysis have improved, resulting in lower detection limits for many trace elements (table 13, supplemental data). Concentrations of some trace elements, such as chromium, silver, and thallium, have largely remained below reporting limits (table 13). Mean unfiltered arsenic concentrations show a decrease in the post-program dataset although the maximum concentration is higher (table 7*D*). Similarly, mean and median filtered boron and molybdenum concentrations are also lower in the post-program dataset (table 7*D*; fig. 5).

Concentrations of eight TOCs were above reporting limits (table 9). Eighteen other TOCs also were detected at concentrations that were less than laboratory reporting limits but were included in the data tables because most are pharmaceuticals (including antibiotics) and currently have unknown ecotoxicological significance (Daughton and Ternes, 1999; Battaglin and Kolok, 2014). Although treated wastewater effluent has

been included in the water rights acquisition program, permits for discharge of treated effluent to both the Truckee and Carson Rivers had been granted prior to enactment of the acquisition program.

Considering the dataset as a whole, aquatic-life criteria and (or) guidelines (table 8) were exceeded at least once for aluminum, arsenic, boron, cadmium, copper, molybdenum, and mercury (tables 11 to 13, supplemental data). The aluminum criterion was exceeded primarily in unfiltered samples. The arsenic criterion was most frequently exceeded in samples collected from Paiute Drain (fig. 2, site 6), represented in the pre-program dataset; the one post-program sample collected from site 6 did not exceed the criterion. Two samples from Lower Diagonal Drain (site 1) had the highest arsenic concentrations (greater than 350 µg/L), but most samples (including most from site 6) did not exceed the continuous National Recommended Criterion (150 µg/L). Concentrations of boron exceeded the aquatic-life criterion (550  $\mu$ g/L) adopted by the State of Nevada most frequently, and in at least one sample collected at each site; however, currently there are no National Recommended Criteria. Cadmium concentrations exceeded the National Recommended Continuous Criterion (0.72 µg/L) in all post-program samples from site 1, and the State of Nevada 96-hour criterion (2 µg/L) was exceeded in two preprogram samples from site 6, with one exceeding the 1-hour criterion (8 µg/L). The aquatic-life 96-hour criterion for copper (10  $\mu$ g/L) was exceeded in two pre-program samples from site 6, one post-program sample from site 1, and two postprogram samples from site 3. The aquatic-life 1-hour criterion  $(15 \,\mu\text{g/L})$  was exceeded in most samples from site 1 (10/11), site 3 (3/5), site 5 (6/6), and site 6 (33/38). The 96-hour average aquatic-life criterion for mercury (0.012  $\mu$ g/L) was exceeded in all 20 unfiltered samples analyzed with a reporting limit of less than 0.00004  $\mu$ g/L (less than 0.04 ng/L), and 14 of the 17 filtered samples also exceeded the criterion. Nine of 30 samples analyzed with a 0.1  $\mu$ g/L (less than 100 ng/L) reporting limit exceeded the mercury criterion, and the National Recommended Maximum Criterion (1.4  $\mu$ g/L) was exceeded in four samples (three from site 5 and one from site 6). Guidance for concentrations of methylmercury has not been promulgated.

Bottom-sediment concentrations (table 15, supplemental data) of arsenic, chromium, copper, lead, nickel, and zinc all were less than published probable effect concentrations (33, 111, 149, 128, 48.6, and 459 milligrams per kilogram (mg/kg), respectively; Ingersoll and others, 2000), but concentrations of mercury in six of nine bottom-sediment samples exceeded the probable effect concentration (1,060 micrograms per kilogram [1.06 mg/kg]).

**Table 7**. Summary statistics for selected constituents in water and bottom-sediment samples collected for the pre- (water years

 1971–98) and post- (water years 2014–16) water rights acquisition program, Stillwater National Wildlife Refuge, Lahontan Valley, Nevada.

 $[Abbreviations: ft^{j}/s, cubic feet per second; ^{o}C, degrees Celsius; \mu S/cm, microsiemens per centimeter; mg/L, milligrams per liter; mv, millivolts; mm, millimeters; \mu g/L, micrograms per liter; ng/L, nanograms per liter; mg/kg, milligrams per kilogram; \mu g/kg, micrograms per kilogram; NA, not applicable; <, less than]$

<sup>1</sup> Nevada Administrative Code 445A (last updated January 6, 2015); accessed December 3, 2016, at https://www.leg.state.nv.us/nac/NAC-445A.html.

<sup>2</sup> U.S. Environmental Protection Agency (2014); accessed December 3, 2016, at

http://water.epa.gov/scitech/swguidance/standards/criteria/current/index.cfm#altable.

<sup>3</sup> Criterion is pH and temperature dependent (NAC445A.118).

<sup>4</sup> Criterion is hardness dependent. Values shown are computed for a hardness of 100 milligrams per liter as calcium carbonate. Greater hardness concentrations mitigate toxicity.

<sup>5</sup> Criterion is for chromium (VI).

<sup>6</sup> Criterion is for chromium (III).

<sup>7</sup> Criterion is calculated using the Biotic Ligand Model and 10 water-quality constituents; accessed December 1, 2016, at http://water.epa.gov/scitech/swguidance/standards/criteria/aqlife/copper/2007\_index.cfm.

<sup>8</sup> Criterion calculated using "intermittent exposure equation"; accessed December 1, 2016, at https://www.epa.gov/sites/production/files/2016-06/documents/se\_2016\_fact\_sheet\_final.pdf.

# **Supplemental Data**

The following tables are distributed as part of this report in Microsoft® Excel 2010 format and are available for download at <a href="https://doi.org/10.3133/ds20171072">https://doi.org/10.3133/ds20171072</a>.

 Table 10.
 Data from field measurements of physical and chemical parameters made at surface-water sites in and near Stillwater

 National Wildlife Refuge, Lahontan Valley, Nevada, 1986–2016.

**Table 11.** Results of analyses for organic carbon, water hardness, major dissolved chemical constituents, and dissolved solids in samples collected from surface-water sites in and near Stillwater National Wildlife Refuge, Lahontan Valley, Nevada, 1986–2016.

**Table 12.** Results of analyses for selected nutrients in samples collected from surface-water sites in and near Stillwater National

 Wildlife Refuge, Lahontan Valley, Nevada, 1986–2016.

**Table 13.** Results of analyses for selected trace elements in samples collected from surface-water sites in and near StillwaterNational Wildlife Refuge, Lahontan Valley, Nevada, 1971–2016.

**Table 14.**Results of analyses for selected trace organic compounds in samples collected from surface-water sites in and nearStillwater National Wildlife Refuge, Lahontan Valley, Nevada, 2014–16.

 
 Table 15.
 Results of analyses for selected trace elements and moisture content in bottom-sediment samples collected from surfacewater sites in and near Stillwater National Wildlife Refuge, Lahontan Valley, Nevada, 2014–16.
